Introducing: Modelling long-term dynamics of MPB in Alberta under climate change

Dr. Mark Lewis and Dr. Micah Brush

Increased mortality of trees, arising from climate change, is occurring worldwide. The capacity of forests to respond to future change is not known, especially when involving both direct and indirect climate-driven stressors. Forests in western Canada are being subjected to the direct climate effects of high temperatures and drought and to the indirect climate effects of climate-driven spread of mountain pine beetle (MPB). To complicate matters, the recent spread of MPB across Alberta has shifted from lodgepole pine hosts to genetically distinct lodgepole x jack pine hybrid and pure jack pine stands in the boreal forest. In recent years, this spread through the hybrid and jack pine stands has been intermittent, distinct from the sustained spread seen earlier in lodgepole pine hosts. Research suggests that survivors of MPB attacks may be genetically distinct from those who succumb, based on having superior defenses. This implies that the beetles themselves are an agent of selection on tree genetics. The question then arises as to the long-term dynamics of MPB in hybrid and jack pine forests of Alberta, especially in the context of stresses driven by the changing climate.

Objectives

1. Develop and apply models to estimate changes in long-term susceptibility and resilience of forest stands to MPB in the presence of intermittent MPB outbreaks and climate change.
2. Develop and apply models to determine the impact of intermittent MPB outbreaks and climate change on persistence of low-level endemic beetle populations.

Federal-Provincial MPB Research Partnership

Mountain Pine Beetle remains a severe threat to Alberta's pine forests despite the province making positive progress in controlling its spread within the province and reducing the risk to the rest of Canada.

Natural Resources Canada and Alberta Agriculture and Forestry have provided funding to a suite of projects with the goals of limiting the spread of Mountain Pine Beetle and mitigating damages where it has already invaded.

Expected Outcomes

We will develop stand productivity models (dynamical systems) and machine learning models to estimate long-term susceptibility and resilience as well as the impacts of intermittent outbreaks on low-level endemic populations. These models will be parameterized to an extensive Alberta dataset. Models will be made available as R code and, where possible, will be integrated into the SpaDES platform for developing and running integrated simulation models for MPB. We will give workshops for end-users.

Implications for Land Management

The results of this modelling will provide a valuable tool for discussion with stakeholders and rights holders. Model predictions will be incorporated in the presentation of alternative scenarios to determine risk and social preferences for different management options of forests, and to determine the long-term impact of MPB on forest ecosystems in Alberta.

Expected Social, Economic, and Ecological Value

MPB expansion into Alberta has cost the province over $568M in management expenses alone. This research will provide a means to predict and evaluate the long-term impact of MPB on forest ecosystems in Alberta.
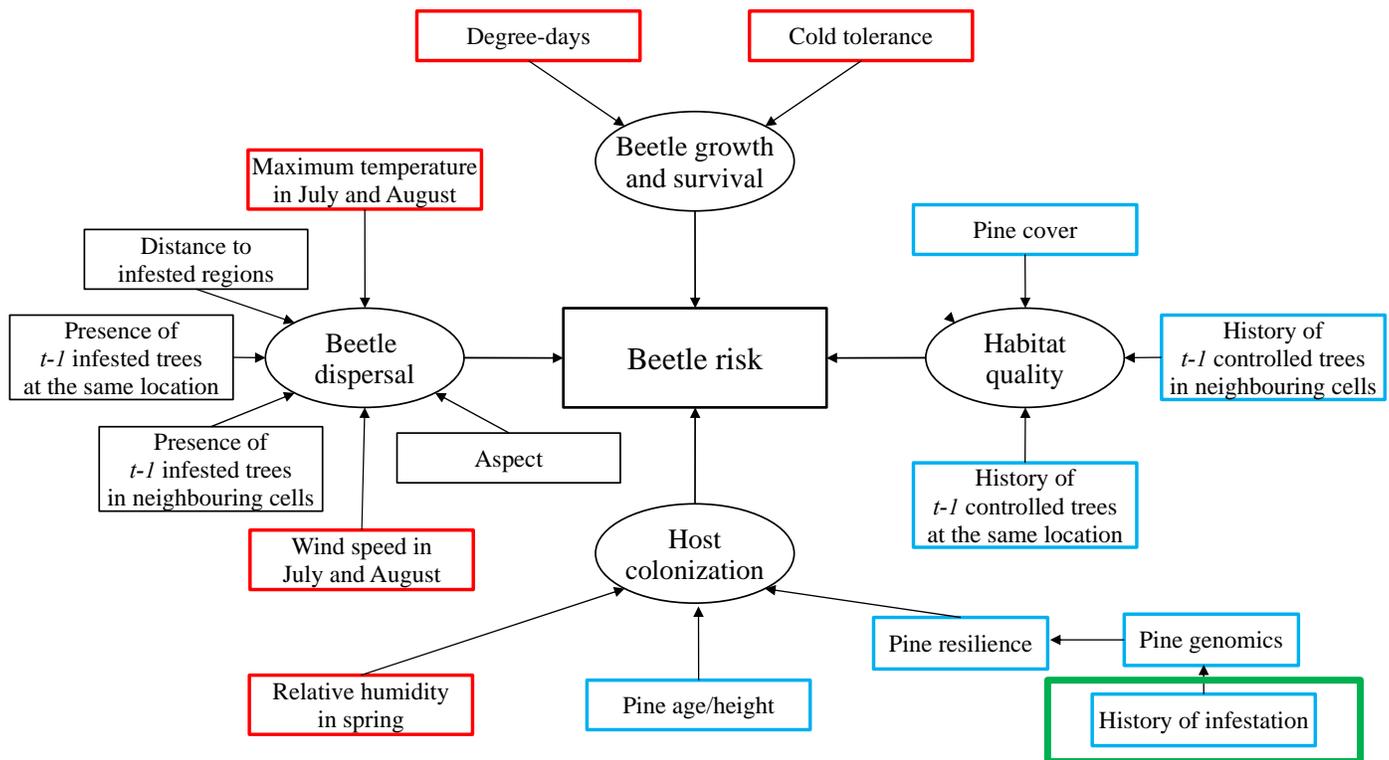

Typical mountain pine beetle risk model based on a literature review. The square boxes represent the independent covariates and dependent variables; the circles represent the latent variables or categories. Typical risk models only use a subset of these depending on the question asked and the data available. Red boxes can be directly impacted by climate change. Blue boxes can be directly impacted by management. The green box shows that history of infestation itself can affect pine genomics, which then has an impact on beetle risk. Few risk models to date have included this range factors.
